Abstract

Exchange rates have raised the ire of economists for more than 20 years. The problem is that few, if any, exchange rate models are known to systematically beat a naive random walk in out of sample forecasts. Engel and West (2005) show that these failures can be explained by the present value model (PVM) because it predicts random walk exchange rate dynamics if the discount factor approaches one and fundamentals have a unit root. This paper broadens and generalizes the Engel and West (EW) hypothesis. We use standard time series tools to broaden analysis of the PVM. For example, our analysis exploits a common feature implication of the PVM and a discount near unity to show that the exchange rate follows a random walk. A PVM of the exchange rate is also constructed from an open economy dynamic stochastic general equilibrium (DSGE) model. The DSGE-PVM predicts that the exchange rate exhibits random walk behavior. Bayesian estimates reveal that the Canadian dollar-U.S. dollar exchange rate is dominated by permanent monetary and productivity shocks as the discount factor becomes close to one. Thus, our results generalize the EW hypothesis to the larger class of open economy DSGE models, while presenting new challenges for future research.

JEL Classification Number: E31, E37, and F41

Key Words: Exchange rates; present-value model; random walk; DSGE model unobserved components.

1. **INTRODUCTION**

The search for satisfactory exchange rate models continues to be elusive. Since the seminal work of Meese and Rogoff (1983a, 1983b), a train of models have been tried in vain to improve on naive random walk forecasts of exchange rates. These range from linear rational expectations models examined by Meese (1986) to nonlinear models proposed by Diebold and Nason (1990), Meese and Rose (1991), Gençay (1999), and Kilian and Taylor (2003).

The *Journal of International Economics* volume edited by Engel, Rogers, and Rose (2003) indicates that there has been a split between theoretical exchange rate models and what is considered a useful forecasting model. For example, Kilian and Taylor (2003) argue that there are specific nonlinear forecasting models that can vie with a naive random walk of exchange rates. This approach maybe useful to obtain candidates for a forecast competition. Nonetheless, there are limits because, as Diebold and Nason (1990) note, the class of nonlinear exchange rate models might be infinite.

This paper steps back from the exchange rate forecasting problem. Rather, we study a workhorse theory of currency market equilibrium determination, the present-value model (PVM) of exchange rates. Actual data most often rejects the exchange rate PVM. Typical are tests Meese (1986) reported that are based on the first ten years of the floating rate regime. He finds that exchange rates are infected with persistent deviations from fundamentals, which reject the PVM and its cross-equation restrictions. However, Meese is unable to uncover the source of the rejections. Instead of a condemnation of the PVM, we view results such as Meese’s as a challenge to update and deepen analysis of the PVM.

Engel and West (2005) take a similar position. Starting with the PVM and using uncontroversial assumptions about fundamentals and the discount factor, Engel and West (EW) hypothesize that the PVM generates an approximate random walk in exchange rates if currency traders are highly interest rate sensitive and fundamentals are $I(1)$. An important implication of the EW hypothesis is that fundamentals through date $t$ have no power to forecast the future path of the exchange rate although the PVM dictates equilibrium in the currency market. EW support their hypothesis with a key theorem and empirical and simulation evidence.
This paper complements Engel and West (2005). We broaden and generalize the EW hypothesis. Standard time series tools are used to broaden the EW hypothesis to show that the standard-PVM predicts a random walk in the exchange rate when it and fundamentals share a common feature. We extend and generalize analysis of the PVM by linearizing and solving the uncovered interest rate parity (UIRP) condition and money demand function of a canonical monetary dynamic stochastic general equilibrium (DSGE) model. The linearized UIRP and money demand equations yield the DSGE-PVM, which we use to generalize the EW hypothesis. Table 1 reviews the key elements of the standard- and DSGE-PVMs.

Table 2 summarizes eight propositions that generalize the EW hypothesis. The first five propositions are constructed from the standard-PVM of the exchange rate, given fundamentals are $I(1)$ and fundamental growth has a Wold representation. The propositions are: (1) the exchange rate and fundamental cointegrate [Campbell and Shiller (1987)], (2) the PVM yields an error correction model (ECM) for currency returns in which the lagged cointegrating relation is the only regressor, (3) if fundamental growth depends only on the lagged cointegrating relation, the exchange rate and fundamental have a common trend-common cycle decomposition [Vahid and Engle (1993)], (4) the PVM predicts a limiting economy (i.e., the PVM discount factor approaches one from below) in which the exchange rate is a martingale, and (5) the EW hypothesis is also satisfied in the limiting economy of (4) when the exchange rate and fundamental fail to cointegrate, but share a common feature. We report evidence using Canadian–, Japanese–, and U.K.–U.S. samples that reject (1), (3), but support (5). This represents more support for the EW hypothesis because we find a common feature exists between the Canadian dollar–, Yen–, and Pound–U.S. dollar exchange rates and the relevant fundamentals.

We generalize the EW hypothesis to the DSGE-PVM. Two propositions extend propositions (1) and (4) to the DSGE-PVM. We also show DSGE-PVM supports the EW hypothesis of proposition (5). A corollary is that the exchange rate is unpredictable when the DSGE-PVM discount factor goes to one. Thus, the standard- and DSGE-PVMs share many predictions. However, the DSGE-PVM suggests a richer set of testable restrictions because the class of open economy monetary DSGE models is large.

The DSGE-PVM imposes cross-equation restrictions on the exchange rate and fundamentals.
The observable fundamentals are cross-country money and consumption for the DSGE-PVM that we restrict with permanent-transitory decompositions. Under this assumption, the DSGE-PVM is cast as an unobserved components (UC) model. The UC model incorporates DSGE-PVM cross-equation restrictions conditional on whether the DSGE-PVM discount factor is calibrated or estimated. Three UC models calibrate the DSGE-PVM discount factor to one, which disconnects the exchange rate from transitory fundamentals. Transitory fundamentals restrict the exchange rate in three other UC models that estimate the DSGE-PVM discount factor. Within this dichotomy of the DSGE-PVM discount factor, six UC models are identified by restrictions on transitory cross-country money and consumption shocks.

We estimate six UC models on a Canadian-U.S. sample running from 1976Q1 to 2004Q4. The UC model yields a state space system for the DSGE-PVM, which allows us to exploit the Kalman filter to evaluate the likelihood. We compute likelihoods of the UC models using the Metropolis-Hastings (MH) simulator of Rabanal and Rubio-Ramírez (2005) to draw Markov chain Monte Carlo (MCMC) replications from the posteriors. The Canadian-U.S. data favor the UC model that calibrates the DSGE-PVM discount factor to one with the only transitory shock to cross-country consumption. Next is the UC model with the same transitory shock, but the estimated posterior mean of the DSGE-PVM discount factor is 0.9962. The posterior of this UC model reveals that permanent shocks to fundamentals dominate Canadian dollar–U.S. dollar exchange rate fluctuations. Thus, the Canadian-U.S. data prefer UC models that are consistent with the EW hypothesis. Further, we find that the Canadian-U.S. data fail to support UC models that tie the exchange rate to the transitory monetary shock. Rogoff (2007) also notes that exchange rates appear disconnected from ‘mean reverting monetary fundamentals’, but our results are still puzzling because of the key roles assigned to nominal rigidities, UIRP shock persistence, and monetary disturbances in open economy monetary DSGE models.

The outline of the paper follows. The next section solves the standard-PVM of the exchange rate and presents its five propositions. Section 3 constructs the DSGE-PVM and discusses its three propositions. Our Bayesian econometric strategy is discussed in section 4. Section 5 reports the posterior estimates of the six UC models. We conclude in section 6.
2. **The Standard Present-Value Model of Exchange Rates**

The standard-PVM determines the equilibrium exchange rate by combining a liquidity-money demand function, uncovered interest rate parity (UIRP) condition, purchasing power parity (PPP), and flexible prices. This is a workhorse exchange rate model used by, among others, Dornbusch (1976), Bilson (1978), Frankel (1979), Meese (1986), Mark (1995), and Engel and West (2005).

The standard-PVM of the exchange rate starts with the liquidity-money demand function

\[ m_{h,t} - p_{h,t} = \psi y_{h,t} - \phi r_{h,t}, \quad 0 < \psi, \phi, \]

where \( m_{h,t} \), \( p_{h,t} \), \( y_{h,t} \), and \( r_{h,t} \) denote the home country’s natural logarithm of money stock, price level, output, and the level of the nominal interest rate. The parameter \( \psi \) measures the income elasticity of money demand. Since the nominal interest rate is in its level, \( \phi \) is the interest rate semi-elasticity of money demand. Define cross-country differentials \( m_t = m_{h,t} - m_{f,t} \), \( p_t = p_{h,t} - p_{f,t} \), \( y_t = y_{h,t} - y_{f,t} \), and \( r_t = r_{h,t} - r_{f,t} \), where \( f \) denotes the foreign country. Assuming PPP holds, \( e_t = p_t \), where \( e_t \) is the log of the (nominal) exchange rate in which the U.S dollar is the home country’s currency.

Under UIRP, the law of motion of the exchange rate is approximately

\[ E_t e_{t+1} - e_t = r_t. \]

Substitute for \( r_t \) in the law of motion of the exchange rate (2) with the money demand function (1) and impose PPP to produce the Euler equation \( e_t - \omega E_t e_{t+1} = (1 - \omega) z_t \), where the standard-PVM discount factor is \( \omega \equiv \frac{\phi}{1 + \phi} \) and \( z_t \equiv m_t - \psi y_t \) is the standard-PVM fundamental, which nets cross-country money with its income demand. Iterate on the Euler equation through date \( T \) and recognize that the transversality condition \( \lim_{T \to \infty} \omega^{T+1} E_t e_{t+T} = 0 \) to obtain the present-value relation

\[ e_t = (1 - \omega) \sum_{j=0}^{\infty} \omega^j E_t z_{t+j}. \]

The present-value relation (3) sets the log exchange rate equal to the annuity value of the fundamental \( z_t \) at the standard-PVM discount factor \( \omega \equiv \frac{\phi}{1 + \phi} \).

\[ ^1 \text{The present-value relation (3) yields the weak prediction that } e \text{ Granger-causes } z. \text{ Engel and West (2005) and Rossi (2007) report that this prediction is often not rejected in G-7 data.} \]
2a. Cointegration Restrictions

The present-value relation (3) provides several predictions given

**Assumption 1**: \( z_t \sim I(1) \).

**Assumption 2**: \((1 - L)z_t\) has a Wold representation, \((1 - L)z_t = \Delta z^* + \zeta(L)\upsilon_t\), where \(Lz_t = z_{t-1} \).\(^2\)

Given Assumptions 1 and 2, the first prediction is that \(e_t\) and \(z_t\) share a common trend. This follows from subtracting the latter from both sides of the equality of the present-value relation (3) and combining terms to produce the exchange rate-fundamental cointegrating relation

\[
(4) \quad e_t - z_t = \sum_{j=1}^{\infty} \omega^j E_t \Delta z_{t+j}, \quad \Delta \equiv 1 - L.
\]

Equation (4) reflects the forces - expected discounted value of fundamental growth - that push the exchange rate toward long-run PPP.

**Proposition 1**: If \(z_t\) satisfies Assumptions 1 and 2, \(X_t = \beta'q_t\) forms a cointegrating relation with cointegrating vector \(\beta' = [1 \quad -1]\), where \(q_t \equiv [e_t \quad z_t]'\).

The proposition is a variation of results found in Campbell and Shiller (1987). Note that the cointegrating relation becomes \(X_t = \zeta(\omega)\upsilon_t\), under Assumptions 1 and 2.

The cointegrating relation \(X_t\) equals the expected present discounted value of \(\Delta m_t\) minus \(\psi \Delta y_t\). Thus, \(X_t\) is stationary, given Assumption 1 (i.e., \(m_t\) and \(y_t\) are \(I(1)\) and fail to share a common trend). We interpret \(X_t\) as the ‘adjusted’ exchange rate because it eliminates cross-country money stock movements netted for its income demand. The ‘adjusted’ exchange rate is a forward-looking function of the expected path of fundamental growth. This suggests the cointegrating relation is a “cycle generator”, as described by Engle and Issler (1995), with the serial correlation of fundamental growth its source.

2b. Equilibrium Currency Return Dynamics

The second PVM prediction begins by writing the present-value relation (3) as

\(^2\)The restrictions on the moving average are \(\Delta z^*\) is linearly deterministic, \(\zeta_0 = 1\), \(\zeta(L)\) is an infinite order lag polynomial with roots outside the unit circle, the \(\zeta_i\)s are square summable, and \(\upsilon_t\) is mean zero, homoskedastic, linearly independent given history and is serially uncorrelated with itself and the past of \(\Delta z_t\). Assumption 2 restricts fundamentals more than Engel and West (2005) require, but is standard for linear rational expectation models; see Hansen, Roberds, and Sargent (1991).
\[ e_t - (1 - \omega)z_t = (1 - \omega) \sum_{j=1}^{\infty} \omega^j E_t z_{t+j}. \]

Next, difference this equation, \( \Delta e_t - (1 - \omega)\Delta z_t = (1 - \omega) \sum_{j=1}^{\infty} \omega^j [E_t z_{t+j} - E_{t-1} z_{t+j-1}] \), add and subtract \( E_t z_{t+j-1} \) inside the brackets, and use the present-value relation (4) to obtain

\[ \Delta e_t - \frac{1 - \omega}{\omega} X_{t-1} = (1 - \omega) \sum_{j=0}^{\infty} \omega^j [E_t - E_{t-1}] z_{t+j}. \]

(5)

Currency returns are driven by the lagged cointegrating relation and innovations to fundamentals.

**Proposition 2:** Assume Proposition 1 holds. The PVM predicts that in equilibrium \( \Delta e_t \sim ECM(0) \), an error correction model in which only the lagged cointegrating relation and forecast innovation appears.

The ECM(0) of currency returns is \( \Delta e_t = \vartheta X_{t-1} + u_{\Delta e,t} \), where \( \vartheta = \frac{1 - \omega}{\omega} \) and the present-value term of equation (5) is \( u_{\Delta e,t} = (1 - \omega) \zeta(\omega) v_t \), under Assumption 2.3.

2c. The Common Trend and Common Cycle of Exchange Rates and Fundamentals

Proposition 2 provides an easy method to compute a BNSW common trend-common cycle decomposition for \( q_t \). Given \( \Delta z_t \) is also an ECM(0), a BNSW decomposition of \( q_t \) relies on the cointegrating vector \( \beta' \) and the relationship between currency returns and fundamental growth.

**Proposition 3:** Assume fundamental growth has an ECM(0) process \( \Delta z_t = \eta X_{t-1} + u_{\Delta z,t} \), where the forecast innovation \( u_{\Delta z,t} \) is Gaussian. Given Proposition 2, \( q_t \) has a common feature, \( f_t = \overline{\beta}' \Delta q_t \), in the sense of Engle and Kozicki (1993), where \( \overline{\beta}' = [1 - \frac{\vartheta}{\eta}] \). The cointegrating and common feature vectors \( \beta \) and \( \overline{\beta} \) restrict the trend-cycle decomposition of \( q_t \), as described by Vahid and Engle (1993).

The currency return-fundamental growth common feature is apparent in the VECM(0)

\[
\begin{bmatrix}
\Delta e_t \\
\Delta z_t
\end{bmatrix} =
\begin{bmatrix}
\vartheta \\
\eta
\end{bmatrix}
X_{t-1} +
\begin{bmatrix}
u_{\Delta e,t} \\
u_{\Delta z,t}
\end{bmatrix}.
\]

Pre-multiply the bivariate ECM(0) by \( \overline{\beta}' \) to obtain the common feature vector \( f_t \). According to Engle and Kozicki (1993), \( \overline{\beta} \) creates a common feature in \( \Delta q_t \) because a linear combination of \( \Delta e_t \) and \( \Delta z_t \) are

3The error \( u_{\Delta e,t} \) is also justified if the econometrician’s information set is strictly within that of currency traders.
unpredictable based on the relevant history (i.e., \( u_{\Delta e,t} \) and \( u_{\Delta z,t} \) are uncorrelated at all non-zero leads and lags). Hecq, Palm, and Urbain (2006) note that \( f_t \) restricts the spectra of \( \Delta q_t \) to be flat.

Proposition 3 predicts \( q_t = [e_t \ z_t]' \) has a BNSW decomposition with one common trend and one common cycle. This mimics a result in Vahid and Engle (1993), which sets the trend of \( q_t \) to \( I_2 - \beta (\beta' \beta)^{-1} \beta' \).

These restrictions decompose \( e_t \) into trend and cycle components \( \frac{-\omega \eta}{1 - \omega (1 + \eta)} \beta' q_t \) and \( \frac{1 - \omega}{1 - \omega (1 + \eta)} \beta' q_t \), respectively. Since \( \Delta e_t \) and \( \Delta z_t \) share a strong form common feature, the cycles common to \( e_t \) and \( z_t \) arise in the short-, medium-, and long-run. Thus, no long-run predictability exists for the exchange rate. A prediction at odds with the empirical evidence of Mark (1995).

2d. A Limiting Model of Exchange Rate Determination

Proposition 2 relies on \( \omega < 1 \) to define short- to medium-run currency return dynamics. This raises the question of the impact of relaxing this bound.

**Proposition 4:** The exchange rate approaches a martingale (in the strict sense) as \( \omega \rightarrow 1 \), according to the present-value relation (5) assuming Proposition 1.

Proposition 4 suggests an equilibrium path for \( e_{t+1} \) in which its best forecast is \( e_t \), given relevant information. The hypothesis of Proposition 4 drives the error \( u_t \) and slope coefficient \( \vartheta \) of the ECM(0) regression to \( u_t \overset{P}{\rightarrow} 0 \) and \( \vartheta \overset{P}{\rightarrow} 0 \), which implies \( E_t e_{t+1} = e_t \). The martingale result implies random walk behavior for the exchange rate.

2e. PVM Exchange Rate Dynamics Redux

Engel and West (2005) show that the PVM of the exchange rate yields an approximate random walk as \( \omega \) approaches one. This section affirms the EW hypothesis, but unlike Proposition 3 does not rely on Proposition 2. Rather than follow the EW proof exactly, we invoke Assumptions 1 and 2, the present-value relation (3), the Weiner-Kolmogorov prediction formula, and the conjecture \( e_t = az_t \) to find that currency returns are unpredictable.

---

4Vahid and Engle show a \( n \)-dimension VAR(1) with \( d \) cointegrating relations has \( n - d \) common feature relations.

6Maheswaran and Sims (1993) show that the martingale restriction has little empirical content for tests of asset pricing models when data is sampled at discrete moments in time.
The EW hypothesis is \( \text{plim}_{\omega} \rightarrow 1 [\Delta e_t - a_\zeta(1) v_t] = 0 \). Its hypothesis test begins by noting \( e_t = z_{t-1} + \sum_{j=0}^{\infty} \omega^j E_t \Delta z_{t+j} \), which is obtained from the present-value relation (3). Use this equation to construct \( \Delta e_t - E_{t-1} \Delta e_t = \zeta(\omega) v_t \), given Assumptions 1 and 2 and the Weiner-Kolmogorov prediction formula. The present-value relation (3) also implies currency returns equal the annuity value of fundamental growth, \( \Delta e_t = (1 - \omega) \sum_{j=0}^{\infty} \omega^j E_t \Delta z_{t+j} \). The last two equations yield

\[
(6) \quad \Delta e_t = \zeta(\omega) v_t + (1 - \omega) \sum_{j=0}^{\infty} \omega^j E_{t-1} \Delta z_{t+j}.
\]

By letting \( \omega \xrightarrow{} 1 \), the random walk hypothesis of EW is verified independent of the ECM(0) of Proposition 2 (and cointegrating relation of Proposition 1).\(^7\)

We show that the EW hypothesis is satisfied by exploiting the common feature implication of the PVM for currency returns and fundamental growth. This result relies on the assumption that \( \Delta q_t \) is \( I(0) \) and has a Wold representation, \( \Delta q_t = \lambda(L) \xi_t \). When \( q_t \) is \( I(1) \) consisting of independent trends, the exchange rate and fundamental possess a bivariate BN decomposition, \( q_t = \lambda(1) \Xi_t + \Lambda(L) \xi_t \), where \( \lambda(1) \) has full rank, \( \Lambda(L) = \sum_{i=0}^{\infty} \Lambda_i \), \( \Lambda_i = - \sum_{j=i+1}^{\infty} \lambda_j \), and \( \Xi_t = \sum_{j=0}^{\infty} \xi_{t-j} \). The bivariate BN decomposition is

\[
(7) \quad \Delta q_t = \lambda(1) \xi_t + \Delta \Lambda(L) \xi_t.
\]

for the currency returns-fundamental growth rate system, which gives us

**PROPOSITION 5:** *The exchange rate-random walk hypothesis of Engel and West (2005) requires currency returns and fundamental growth share a common feature, as well as \( \omega \rightarrow 1 \).*

The EW hypothesis eliminates the BN cycle, \( \Lambda(L) \xi_t \), from equation (7). Serial correlated common cycles are annihilated by the common feature vector \( \overline{\beta}' \), which for the multivariate BN growth rates representation (7) sets \( \overline{\beta}' \Delta q_t = \overline{\beta}' \lambda(1) \xi_t \). All that remains to drive \( \Delta q_t \) is \( \lambda(1) \xi_t \). When \( \overline{\beta}' \xrightarrow{} [1 \ 0] \), Proposition 5 predicts that the limiting behavior of the exchange rate is a random walk driven by its own forecast innovations. Thus, the EW hypothesis is affirmed by Proposition 5. Proposition 5 also reveals that the EW hypothesis is consistent with a common feature restriction on short-, medium-, and long-run movements in the exchange rate and fundamentals.

\(^7\)This analysis matches equations A.3 – A.11 and the surrounding discussion of Engel and West (2005).
2f. Tests of the PVM of the Exchange Rate

Propositions 1, 3, and 5 yield testable restrictions on exchange rates and fundamentals. If the lag length of the levels VAR of the exchange rate and fundamental exceeds one, the VECM(0) required by Proposition 3 is rejected. Cointegration tests suffice to examine Proposition 1. Vahid and Engel (1993) and Engel and Issler (1995) provide common feature tests that yield information about the EW hypothesis and Proposition 5. Table 3 summarizes the results and details the tests involved.

We estimate VARs of foreign currency-U.S. dollar exchange rates and fundamentals using Canadian, Japanese, U.K., and U.S. data on a 1976Q1 – 2004Q4 sample. VAR lag lengths are chosen using likelihood ratio (LR) statistics, given a VAR(8), ..., VAR(1). The Canadian–, Japanese–, and U.K.–U.S. samples yield a VAR(8), VAR(5), and VAR(4), respectively. Thus, the Canadian, Japanese, U.K., and U.S. data reject a weak implication of Proposition 3.

Engel and West (2005) argue there is little evidence that exchange rates and fundamentals cointegrate. Table 3 presents Johansen (1991, 1994) trace and $\lambda_{\text{max}}$ statistics that support this conclusion. Since these tests reject a cointegrating relation for the exchange rate and fundamental, we find no evidence to confirm Proposition 3.

Table 3 includes squared canonical correlations of currency returns and fundamental growth. The common feature null is that the smallest correlation equals zero. We use a $\chi^2$ statistic found in Vahid and Engle (1993) and a $F$–statistic suggested by Rao (1973) to test this null. The tests reject the null for the largest canonical correlation, but not for the smaller one on the three samples. This supports Proposition 5 – the EW hypothesis that the exchange rate is a random walk – because currency returns and fundamental growth have a common feature.

---

8Fundamentals equal cross-country money minus cross-country output, which implies an income elasticity of money demand, $\psi$, calibrated to one. This calibration is consistent with estimates reported by Mark and Sul (2003). The money stocks (outputs) are measured in current (constant) local currency units and per capita terms.

9The VARs include a constant and linear time trend. The LR statistics employ the Sims (1980) correction and have standard asymptotic distribution according to results in Sims, Stock, and Watson (1990).

10The Canadian-U.S. and Japanese-U.S. VARs are selected when the $p$–value of the LR test is five percent or less. Since the U.K.-U.S. VAR offers ambiguous results, we settle on a VAR(4).
3. **THE DSGE PRESENT-VALUE MODEL OF THE EXCHANGE RATE**

Propositions 1 - 5 broaden our understanding of the EW hypothesis. Standard time series tools are used to obtain restrictions on the joint behavior of exchange rates and fundamentals from the standard-PVM. For example, Proposition 1 predicts that the exchange rate and fundamentals cointegrate. However, we estimate VARs that reject the common trend prediction for the Canadian dollar-, Yen-, or Pound-U.S. dollar exchange rate and fundamentals. The estimated VARs also expose greater serial correlation in these series than predicted by the currency returns-fundamental growth VECM(0) of Proposition 3. Nonetheless, we find currency returns and fundamental growth share a common feature in the Canadian-, Japanese-, U.K.-U.S. data which supports the EW random walk hypothesis.

Rejection of the PVM is often given as a reason to discard linear rational expectations models of exchange rates. This paper does not. In this section, we develop a PVM model of the exchange rate derived from a canonical optimizing two-country monetary DSGE model. Our aim is to generalize the PVM and EW hypothesis to this wider class of DSGE models. We meet this goal with the DSGE-PVM which yields an equilibrium exchange rate model whose short-, medium-, and long-run predictions are testable on actual data. We address the empirical implications of the DSGE-PVM in the next two sections.

3a. **The DSGE Model**

The optimizing monetary DSGE model consists of the preferences of domestic and foreign economies and their resource constraints. For the home (h) and foreign (f) countries, the former objects take the form

\[ U \left( C_{i,t}, \frac{M_{i,t}}{P_{i,t}} \right) = \frac{C_{i,t}^{\nu} \left( \frac{M_{i,t}}{P_{i,t}} \right)^{(1-\nu)} \left( 1 - \varphi \right)}{1 - \varphi}, \quad 0 < \nu < 1, \quad 0 < \varphi, \]

where \( C_{i,t} \) and \( M_{i,t} \) represent the \( i \)th country’s consumption and the \( i \)th country’s holdings of its money stock. The resource constraint of the home country is

\[ B_h + s_t B_{h,t-1} + P_{h,t} C_{h,t} + M_{h,t} = (1 + r_{h,t-1}) B_{h,t-1} + s_t (1 + r_{f,t-1}) B_{f,t-1} + M_{h,t-1} + P_{h,t} Y_{h,t}, \]

where \( B_{h,t}, B_{f,t}, r_{h,t}, r_{f,t}, Y_{i,t}, \) and \( s_t \) denote the \( i \)th country’s nominal holding of its own bonds at
the end of date \( t \), the \( i \)th country’s nominal holding of the \( \ell \)th country’s bonds at the end of date \( t \),
the return on the \( i \)th country’s bond, the return on the \( \ell \)th country’s bond, the output level of the \( i \)th country, and the level of the exchange rate. The two-country DSGE model is closed with
\[ B_{h,t}^h + B_{f,t}^f + B_{f,t}^h + B_{f,t}^f = 0. \]
This condition forces the world stock of nominal debt to be in zero net supply, period-by-period, along the equilibrium path.

In section 2, analysis of the standard-PVM relies on \( I(1) \) fundamentals. Likewise, we assume that the processes for labor-augmenting total factor productivity (TFP), \( A_{i,t} \), and \( M_{i,t} \) satisfy

**Assumption 3:** \( \ln[A_{i,t}] \) and \( \ln[M_{i,t}] \sim I(1), \ i = h, f. \)

**Assumption 4:** Cross-country TFP and money stock differentials are \( I(1) \) and do not cointegrate.

Assumptions 3 and 4 impose stochastic trends on the two-country DSGE model.

### 3b. Optimizing UIRP and Money Demand

The home country maximizes its expected discounted lifetime utility over uncertainty streams of consumption and real balances,

\[ E_t \left\{ \sum_{j=0}^{\infty} (1 + \rho)^{-j} U \left( C_{h,t+j}, \frac{M_{h,t+j}}{P_{h,t+j}} \right) \right\}, \ 0 < \rho, \]

subject to (9). The first-order necessary conditions of economy \( i \) yield optimality conditions that describe UIRP and money demand. The utility-based UIRP condition of the home country is

\[ E_t \left\{ \frac{U_{C,h,t+1}}{P_{h,t+1}} \right\} (1 + r_{h,t}) = E_t \left\{ \frac{U_{C,h,t+1}}{P_{f,t+1}} \right\} \frac{(1 + r_{f,t})}{s_t}, \]

where \( U_{C,h,t} \) is the marginal utility of consumption of the home country at date \( t \). Given the utility specification (8), the exact money demand function of country \( i \) is

\[ \frac{M_{i,t}}{P_{i,t}} = C_{i,t} \left( \frac{1 - \nu}{\nu} \right) \frac{1 + r_{i,t}}{r_{i,t}}, \ i = h, f. \]

The consumption elasticity of money demand is unity, while the interest elasticity of money demand is a nonlinear function of the steady state bond return.
The UIRP condition (10) and money demand equation (11) can be stochastically detrended and then linearized to produce an equilibrium DSGE-law of motion for the exchange rate. Begin by combining the utility function (8) and the UIRP condition (10) to obtain

$$
E_t \left\{ \frac{U_{h,t+1}}{P_{h,t+1}C_{h,t+1}} \right\} (1 + r_{h,t}) = E_t \left\{ \frac{U_{f,t+1}}{P_{f,t+1}C_{h,t+1}} \right\} \frac{(1 + r_{f,t})}{s_t},
$$

where $U_{i,t}$ is the utility level of country $i$ at date $t$. Prior to stochastically detrending the previous expression, define

$$
\hat{U}_{i,t} = U_{i,t} / A_{i,t}, \quad \hat{P}_{i,t} = P_{i,t} A_{i,t} / M_{i,t}, \quad \hat{C}_{i,t} = C_{i,t} / A_{i,t}, \quad \gamma_{A,i,t} = A_{i,t} / A_{i,t-1}, \quad \gamma_{M,i,t} = M_{i,t} / M_{i,t-1}, \quad \hat{s}_t = s_t A_{i,t} / M_{i,t}, \quad A_{t} = A_{h,t} / A_{f,t}, \quad \text{and} \quad M_{t} = M_{h,t} / M_{f,t}.
$$

Note that $\hat{C}_{i,t}$ is the transitory component of consumption of the $i$th economy, $\gamma_{A,i,t}$ ($\gamma_{M,i,t}$) is the TFP (money) growth rate of country $i$, and the cross-country TFP (money stock) differential $A_{t}$ ($M_{t}$) are I(1). Applying the definitions, the stochastically detrended UIRP condition becomes

$$
E_t \left\{ \frac{\hat{U}_{h,t+1} Y_{A,h,t+1}^{1-\rho}}{Y_{M,h,t+1} Y_{f,h,t+1} C_{h,t+1}} \right\} (1 + r_{h,t}) = E_t \left\{ \frac{\hat{U}_{f,t+1} Y_{A,f,t+1}^{1-\rho}}{Y_{M,f,t+1} Y_{f,f,t+1} C_{h,t+1}} \right\} \frac{(1 + r_{f,t})}{\hat{s}_t}.
$$

A log linear approximation of the stochastically detrended UIRP condition yields

$$
E_t \tilde{e}_{t+1} - \tilde{e}_t = \frac{r^*}{1 + r^*} \tilde{r}_t + E_t \left\{ \tilde{y}_{A,t+1} - \tilde{y}_{M,t+1} \right\},
$$

where, for example, $\tilde{e}_t = \ln(\tilde{s}_t) - \ln(s^*)$ and $r^* (= r^*_h = r^*_f)$ denotes the steady state (or population) world real rate, for example.

3c. A DSGE-PVM of the Exchange Rate

We use the linear approximate law of motion of the exchange rate (12), and a stochastically detrended version of the money demand equation (11) to produce the DSGE-PVM. The unit consumption elasticity-money demand equation (11) implies the money demand equation $-\hat{p}_t = \tilde{\zeta}_t - \frac{1}{1 + r^*} \tilde{r}_t$.

Impose PPP on the stochastically detrended version of the money demand equation and combine it with the law of motion (12) of the transitory component of the exchange rate to find

$$
\left[ 1 - \frac{1}{1 + r^*} E_t \mathbf{L}^{-1} \right] \tilde{e}_t = \frac{1}{1 + r^*} E_t \left\{ \tilde{y}_{M,t+1} - \tilde{y}_{A,t+1} \right\} - \frac{r^*}{1 + r^*} \tilde{e}_t.
$$
Solving this stochastic difference equation forward yields the DSGE-PVM

\[
\tilde{c}_t = \sum_{j=1}^{\infty} \kappa^j E_t \{ \tilde{y}_{M,t+j} - \tilde{y}_{A,t+j} \} - (1 - \kappa) \sum_{j=0}^{\infty} \kappa^j E_t \tilde{c}_{t+j},
\]

where the relevant transversality conditions are invoked and the DSGE-PVM discount factor \( \kappa \equiv \frac{1}{1+r^*} \).

Note that the DSGE-PVM and permanent income hypothesis discount factors are equivalent.

The DSGE-PVM relation (13) is the equilibrium law of motion of the cyclical component of the exchange rate. Transitory movements in the exchange rate are equated with the future discounted expected path of cross-country money and TFP growth and the (negative of the) annuity-value of the transitory component of cross-country consumption. The DSGE model identifies the exchange rate's unobserved time-varying risk premium with expected path of cross-country TFP growth and transitory consumption, which suggest additional sources of exchange rate fluctuations.

3d. DSGE-PVM Cointegration Restrictions

The DSGE-PVM produces an ECM of the exchange rate. The cointegrating relation follows from a balanced growth restrictions of the DSGE model, \( e_t = \ln[s_t] = \ln[\hat{s}_t] + m_t - a_t \), where \( m_t = \ln[M_t] \) and \( a_t = \ln[A_t] \). Thus, the DSGE-PVM produces the cointegrating relation

\[
X_{DSGE,t} = \tilde{e}_t + \tilde{c}_t, \quad X_{DSGE,t} = e_t - (m_t - c_t),
\]

where constants are ignored, \( c_t = \ln[C_t] \), and stochastic detrending implies \( a_t = c_t - \tilde{c}_t \).

The ECM reflects the forces that push the exchange rate toward long-run PPP plus sources of short- and medium-run PPP deviations. Persistent PPP deviations depend on the forward-looking component \( \tilde{e}_t \) and transitory date \( t \) cross-country consumption, \( \tilde{c}_t \). Nonetheless, the DSGE-PVM restricts PPP deviations to be stationary, which leads to

**Proposition 6:** If \( m_t \) and \( A_t \) satisfy Assumptions 3 and 4, \( X_{DSGE,t} = \beta'_c q_{DSGE,t} \) forms a cointegrating relation with cointegrating vector \( \beta'_c = [1 -1 1] \), where \( q_{DSGE,t} = [e_t \ m_t \ c_t]' \).

The DSGE-PVM predicts a forward-looking cointegrating relation, but with new sources of transitory dynamics. Unobserved \( \tilde{e}_t \) and \( \tilde{c}_t \) movements create persistence and volatility in the "cycle genera-
tor X_{DSGE,t} of (14). Thus, the DSGE-PVM engages unobserved sources of serial correlated short- and medium-run PPP deviations not found in the standard-PVM to drive exchange rate fluctuations.

3e. DSGE-PVM Equilibrium Currency Return Dynamics

The DSGE model produces an equilibrium currency return generating equation that resembles the standard-PVM (5). Thus, the DSGE model predicts martingale-like behavior for the exchange rate given Assumptions 3 and 4, Proposition 6, and that κ approaches one. This result follows from unwinding the stochastic detrending of the DSGE-PVM (13) to find

\begin{equation}
    e_t = (1 - \kappa) \sum_{j=0}^{\infty} \kappa^j E_t \{ m_{t+j} - c_{t+j} \}.
\end{equation}

Subsequent to some algebra, the levels DSGE-PVM (15) yields the ECM(0)

\begin{equation}
    \Delta e_t - \frac{(1 - \kappa)}{\kappa} X_{DSGE,t-1} = (1 - \kappa) \sum_{j=0}^{\infty} \kappa^j [E_t - E_{t-1}] \{ m_{t+j} - c_{t+j} \}.
\end{equation}

This suggests

**PROPOSITION 7**: Assume $e_t$, $m_t$, and $c_t$ share a common trend. As $\kappa \to 1$, the exchange rate approximates a martingale.

The DSGE model restricts currency returns to follow the ECM(0) of (16). When the DSGE-PVM discount factor near unity, current returns becomes independent of fundamentals. Thus, the DSGE-PVM predicts, as does the standard-PVM, an equilibrium in which the current exchange rate is the best forecast of the future exchange rate, $E_t e_{t+1} = e_t$. Proposition 7 suggests why open economy DSGE models have trouble producing exchange rate forecasts that beat a naive random walk. The exchange rate decouples from fundamentals at a small world real interest rate $r^*$, or $\kappa \to 1$.

The levels DSGE-PVM (15) also generates exchange rate dynamics that satisfy the EW hypothesis. From this version of the DSGE-PVM, it is straightforward to obtain

\begin{equation}
    \Delta e_t = \sum_{j=0}^{\infty} \kappa^j [E_t - E_{t-1}] \{ \Delta m_{t+j} - \Delta c_{t+j} \} + (1 - \kappa) \sum_{j=0}^{\infty} \kappa^j E_t \{ \Delta m_{t+j} - \Delta c_{t+j} \}.
\end{equation}

It is obvious from (17) that as $\kappa$ goes to one currency returns become unpredictable in the forecast
innovations of cross-country money and consumption growth, which verifies the EW hypothesis. We make this explicit by endowing $m_t$ with the permanent component $\mu_t$, where $\mu_{t+1} = m_t + \epsilon_{\mu,t+1}$, $\epsilon_{\mu,t+1} \sim \mathcal{N}(0, \sigma_{\mu}^2)$, and likewise let $a_{t+1} = a_t + \epsilon_{a,t+1}$, $\epsilon_{a,t+1} \sim \mathcal{N}(0, \sigma_a^2)$, which satisfies Assumption 4. Also, take the transitory components of $m_t$ and $c_t$ to be Wold, where $\varsigma_i(L)\varepsilon_i,t$, $i = \tilde{m}, \tilde{c}$ (with $\varsigma_i,0 = 1$).

Applying these permanent-transitory decompositions to (17) produces

$$\Delta e_t = \epsilon_{\mu,t} + \epsilon_{\tilde{m},t} - (\epsilon_{a,t} + \epsilon_{\tilde{c},t}) + (1 - \kappa)\left[1 - \varsigma_{\tilde{m}}(\kappa)\right]\epsilon_{\tilde{m},t}$$

$$- \left[1 - \varsigma_{\tilde{c}}(\kappa)\right]\epsilon_{\tilde{c},t} + \sum_{j=0}^{\infty} \kappa^j E_t \{\Delta m_{t+j} - \Delta c_{t+j}\}.$$

The equilibrium currency return generating equation (18) gives us

**Proposition 8:** Let $m_t$ and $c_t$ have random walk permanent and transitory Wold components. As the DSGE-PVM discount factor $\kappa \to 1$, the exchange rate becomes a random walk driven by contemporaneous innovations to the permanent and transitory components of fundamentals.

Let $\kappa$ go to one (from below). The equilibrium currency return generating equation (18) collapses to $\Delta e_t = \epsilon_{\mu,t} + \epsilon_{\tilde{m},t} - \epsilon_{a,t} - \epsilon_{\tilde{c},t}$. The currency return is white noise tied to innovations in the random walk and transitory Wold components of fundamentals, as the DSGE-PVM discount factor nears one. Thus, Proposition 8 generalizes the EW hypothesis that the exchange rate mimics a random walk to the larger class of DSGE models. A corollary is that changes in fundamentals do not Granger cause currency returns as $\kappa \to 1$. Only if $\kappa \in (0, 1)$ do movements in fundamentals have predictive power for currency returns according to the DSGE-PVM (18). However, currency returns Granger cause growth in fundamentals as long as it is predicted by lags of permanent or transitory innovations to cross-country money and TFP.

The equilibrium currency return generating equation (18) shows that this holds even if $\kappa \to 1$.

In summary, this section constructs and studies a DSGE-PVM of the exchange rate that generalizes the EW hypothesis. We show that the DSGE-PVM predicts the exchange rate and fundamentals cointegrate, an ECM(0) generates equilibrium currency returns, and the exchange rate mimics a random walk as the DSGE-PVM discount factor goes to one. Since the DSGE-PVM predictions match those of the
standard-PVM, we extend the EW hypothesis to the large class of open economy monetary DSGE models. The next two sections describe the empirical content of the DSGE-PVM and draw its implications for a Canadian–U.S. sample.

4. **Econometric Models and Methods**

This section describes the Bayesian methods we employ to estimate six UC multivariate models. The UC models represent different combinations of restrictions imposed by the DSGE-PVM on the exchange rate, cross-country money, and cross-country consumption. For example, \( \kappa \) is estimated for three UC models, which ties the exchange rate to the transitory component(s) of fundamentals. The exchange rate is disconnected from transitory shocks in remaining three UC models because \( \kappa \) is calibrated to one. We cast the UC models in state space form to evaluate numerically the likelihoods on a 1976Q1–2004Q4 sample of the Canadian dollar–U.S. dollar (CDN$/US$) exchange rate and the Canadian–U.S. money and consumption differentials. The random walk MH simulator is used to generate MCMC draws from the UC model posterior distributions conditional on this sample. We compute model moments, such as parameter means, unconditional variance ratios, permanent-transitory decompositions, and forecast error variance decompositions (FEVDs), from the posterior distributions. Model comparisons are based on marginal likelihoods, which we construct by integrating the likelihood function of each model across its parameter space where the weighting function is the model prior.

4a. **State Space Systems of the UC Models**

The state space systems of the six UC models begin with the balanced growth restriction the DSGE model imposes on the exchange rate. This restriction is equivalent to the permanent-transitory decomposition \( e_t = m_t - a_t + \tilde{e}_t \). The DSGE-PVM (13) puts restrictions on the stationary component of the exchange rate, \( \tilde{e}_t \). These elements form the balanced growth version of the DSGE-PVM

\[
(19) \quad e_t = \mu_t - a_t + \sum_{j=0}^{\infty} \kappa^j E_t \left\{ \tilde{m}_{t+j} - \tilde{c}_{t+j} \right\},
\]

which also relies on the DSGE balanced growth path restrictions on cross-country money and consumption. The balanced growth DSGE-PVM (19) implies the cointegrating relation Proposition 6 places on
the exchange rate and cross-country money and consumption. Thus, the exchange rate responds only
to trends in cross-country money, \( \mu_t \), and TFP, \( a_t \), in the long-run. Serial correlation in the exchange
rate is produced by the transitory components of cross-country money and consumption, \( \tilde{m}_t \) and \( \tilde{c}_t \).
Also, note that if a common cycle generates these transitory components, the exchange does shares the
restriction. Thus, the permanent and transitory components of cross-country money and consumption
drive exchange rate fluctuations, which give rise to cross-equations in the UC models.

Cross-equation restrictions are conditioned on the permanent and transitory components of
cross-country money and cross-country consumption. We assume \( \tilde{m}_t \) is a MA(\( k_{\tilde{m}} \)), \( \tilde{m}_t = \sum_{j=0}^{k_{\tilde{m}}} \alpha_j \varepsilon_{\tilde{m},t-j} \),
where \( \alpha_0 = 1 \) and \( \varepsilon_{\tilde{m},t} \sim \mathcal{N}(0, \sigma^2_{\varepsilon_{\tilde{m}}}) \). For \( \tilde{c}_t \), we employ a AR(\( k_{\tilde{c}} \)), \( \tilde{c}_t = \sum_{j=1}^{k_{\tilde{c}}} \theta_j \varepsilon_{\varepsilon_{\tilde{c}},t-j} + \varepsilon_{\varepsilon_{\tilde{c}},t} \), where
\( \varepsilon_{\varepsilon_{\tilde{c}},t} \sim \mathcal{N}(0, \sigma^2_{\varepsilon_{\tilde{c}}}) \). As in the previous section, the permanent components of money and consumption are
\( \mu_{t+1} = \mu^* + \mu_t + \varepsilon_{\mu,t+1}, \varepsilon_{\mu,t+1} \sim \mathcal{N}(0, \sigma^2_{\varepsilon_{\mu}}) \), and \( a_{t+1} = a^* + a_t + \varepsilon_{a,t+1}, \varepsilon_{a,t+1} \sim \mathcal{N}(0, \sigma^2_{\varepsilon_{a}}) \). Note that
\( \mu^* \) and \( a^* \) are the deterministic trend growth rates of cross-country money and TFP.

We classify the UC models according to whether there are two cycles or a common cycle and
whether \( \kappa \) is calibrated to one or estimated. Thus, the DSGE-PVM (19) is solved for the exchange rate
given \( \tilde{m}_t \sim \text{MA}(k_{\tilde{m}}) \) and \( \tilde{c}_t \sim \text{AR}(k_{\tilde{c}}) \) or a common cycle is imposed using either the MA(\( k_{\tilde{m}} \)) or AR(\( k_{\tilde{c}} \)).
We double these three UC models when \( \kappa \) is calibrated to one or not. However, the six UC models have
in common the cross-country money and TFP trends, \( \mu_t \) and \( a_t \).

The richest set of cross-equation restrictions arises in the 2-trend, 2-cycle UC model with \( \kappa \in (0, 1) \). In part, its state space system consists of the observation equations

\[
\begin{bmatrix}
  e_t \\
  m_t \\
  c_t
\end{bmatrix} =
\begin{bmatrix}
  1 & -1 & \delta_{\tilde{m},0} & \delta_{\tilde{m},1} & \ldots & \delta_{\tilde{m},k_{\tilde{m}}} & \delta_{\varepsilon_{\tilde{m}},0} & \delta_{\varepsilon_{\tilde{m}},1} & \ldots & \delta_{\varepsilon_{\tilde{m}},k_{\varepsilon_{\tilde{m}}}} \\
  1 & 0 & 1 & \alpha_1 & \ldots & \alpha_{k_{\tilde{m}}} & 0 & 0 \ldots & 0 \\
  0 & 1 & 0 & 0 \ldots & 0 & 1 & 0 \ldots & 0 \end{bmatrix}
S_{\tilde{m},c,t},
\]

where \( S_{\tilde{m},c,t} = \left[ \begin{array}{llllll}
  \mu_t & a_t & \varepsilon_{\tilde{m},t} & \varepsilon_{\tilde{m},t-1} & \ldots & \varepsilon_{\tilde{m},t-k_{\tilde{m}}} & \tilde{c}_t & \tilde{c}_{t-1} & \ldots & \tilde{c}_{t-k_{\varepsilon_{\tilde{c}}}}
\end{array} \right] \), the factor loadings on \( \varepsilon_{\tilde{m},t} \) and its
lags are
\[ \delta_{\tilde{m},i} = (1 - \kappa) \sum_{j=1}^{k_{\tilde{m}}} \kappa^{j-1} \alpha_j, \quad i = 0, \ldots, k_{\tilde{m}}, \]  

the factor loadings on \( \tilde{c}_t, \ldots, \tilde{c}_{t-k_{\tilde{c}}} \) are elements of the row vector

\[ \delta_{\tilde{c}} = -s_{\tilde{c}}(1 - \kappa) \left[ I_k - \kappa \Theta \right]^{-1}, \quad s_{\tilde{c}} = [1 \ 0_{1 \times k_{\tilde{c}} - 1}], \]

and \( \Theta \) is the companion matrix of the AR(\( k_{\tilde{c}} \)) of \( \tilde{c}_t \). The system of first-order state equations is

\[ S_{\tilde{m},c,t+1} = \begin{bmatrix} \mu^* \\ a^* \\ 0 \\ \vdots \\ 0 \end{bmatrix} + \begin{bmatrix} 1 & 0 & \ldots & 0 & 0 & \ldots & 0 \\ 0 & 1 & \ldots & 0 & 0 & \ldots & 0 \\ 0 & 0 & \ldots & 0 & 0 & \ldots & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \ldots & 0 & \theta_1 & \ldots & \theta_{k_{\tilde{c}}} \\ \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \end{bmatrix} S_{\tilde{m},c,t} + \begin{bmatrix} \varepsilon_{\mu,t+1} \\ \varepsilon_{a,t+1} \\ \varepsilon_{\tilde{m},t+1} \\ \varepsilon_{\tilde{c},t+1} \\ \varepsilon_{\tilde{c},t+1} \end{bmatrix}, \]

with the covariance matrix \( \Omega_{\tilde{m},\tilde{c}} = \varepsilon_{\tilde{m},c,t} \varepsilon'_{\tilde{m},c,t} \) where \( \varepsilon_{\tilde{m},c,t} = [\varepsilon_{\mu,t+1} \varepsilon_{a,t+1} \varepsilon_{\tilde{m},t+1} \varepsilon_{\tilde{c},t+1} \varepsilon_{\tilde{c},t+1}]' \).

We also study the implications of imposing one common transitory factor on \( m_t \) and \( c_t \). When this common component is \( \tilde{m}_t \), the response of \( c_t \) to \( \tilde{m}_t \) is denoted \( \pi_{m,\tilde{c}} \). This implies \( \tilde{c}_t = \pi_{m,\tilde{c}} \tilde{m}_t = \pi_{m,\tilde{c}} \sum_{j=0}^{k_{\tilde{m}}} \alpha_j \varepsilon_{\tilde{m},t-j} \). For the 2-trend, money cycle UC model, the state vector and observer system are

\[ S_{\tilde{m},t} = \begin{bmatrix} \mu_t & \alpha_t & \varepsilon_{\tilde{m},t} & \varepsilon_{\tilde{m},t-1} & \ldots & \varepsilon_{\tilde{m},t-k_{\tilde{m}}} \end{bmatrix}' \]

and

\[ \begin{bmatrix} e_t \\ m_t \\ c_t \end{bmatrix} = \begin{bmatrix} 1 & -1 & (1 - \pi_{c,\tilde{m}}) \delta_{\tilde{m},0} & (1 - \pi_{c,\tilde{m}}) \delta_{\tilde{m},1} & \ldots & (1 - \pi_{c,\tilde{m}}) \delta_{\tilde{m},k_{\tilde{m}}} \\ 1 & 0 & 1 & \alpha_1 & \ldots & \alpha_{k_{\tilde{m}}} \\ 0 & 1 & \pi_{c,\tilde{m}} & \pi_{c,\tilde{m}} \alpha_1 & \ldots & \pi_{c,\tilde{m}} \alpha_{k_{\tilde{m}}} \end{bmatrix} S_{\tilde{m},t}, \]

respectively. The state equation of this system is
\[
S_{\tilde{m},t+1} = \begin{bmatrix}
\mu^* \\
ap^* \\
0 \\
\vdots \\
0 \\
\end{bmatrix} + \begin{bmatrix}
1 & 0 & 0 & \ldots & 0 & 0 \\
0 & 1 & 0 & \ldots & 0 & 0 \\
0 & 0 & 0 & \ldots & 0 & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\
0 & 0 & 0 & \ldots & 1 & 0 \\
\end{bmatrix} S_{\tilde{m},t} + \begin{bmatrix}
\varepsilon_{\mu,t+1} \\
\varepsilon_{a,t+1} \\
0 \\
\vdots \\
0 \\
\end{bmatrix}
\]

with covariance matrix \(\Omega_{\tilde{m}} = \varepsilon_{\tilde{m},t}\varepsilon'_{\tilde{m},t}\), where \(\varepsilon_{\tilde{m},t} = [\varepsilon_{\mu,t+1} \ \varepsilon_{a,t+1} \ \varepsilon_{\tilde{m},t+1} \ 0 \ldots 0]'\).

Identifying the common transitory component with \(\tilde{c}_t\) restricts \(\tilde{m}_t = \pi_{m,\tilde{c}}\tilde{c}_t\). This yields the system of observer equations of the 2-trend, consumption cycle UC model

\[
\begin{bmatrix}
e_t \\
m_t \\
c_t
\end{bmatrix} = \begin{bmatrix}
1 & -1 & (1 - \pi_{m,\tilde{c}})\delta_{\tilde{c},0} & (1 - \pi_{m,\tilde{c}})\delta_{\tilde{c},1} & \ldots & (1 - \pi_{m,\tilde{c}})\delta_{\tilde{c},k-1}
\end{bmatrix} S_{\tilde{c},t},
\]

and the system of state equations

\[
S_{\tilde{c},t+1} = \begin{bmatrix}
\mu^* \\
ap^* \\
0 \\
\vdots \\
0 \\
\end{bmatrix} + \begin{bmatrix}
1 & 0 & 0 & \ldots & 0 & 0 \\
0 & 1 & 0 & \ldots & 0 & 0 \\
0 & 0 & \theta_1 & \theta_2 & \ldots & \theta_{k-1} & \theta_k \\
\vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\
0 & 0 & 0 & 0 & \ldots & 1 & 0 \\
\end{bmatrix} S_{\tilde{c},t} + \begin{bmatrix}
\varepsilon_{\mu,t+1} \\
\varepsilon_{a,t+1} \\
\varepsilon_{\tilde{c},t+1} \\
\vdots \\
0 \\
\end{bmatrix}
\]

where \(S_{\tilde{c},t} = [\mu_t \ a_t \ \tilde{c}_t \ \tilde{c}_{t-1} \ \ldots \ \tilde{c}_{t-k+1}]'\), \(\Omega_{\tilde{c}} = \varepsilon_{\tilde{c},t}\varepsilon'_{\tilde{c},t}\), and \(\varepsilon_{\tilde{c},t} = [\varepsilon_{\mu,t+1} \ \varepsilon_{a,t+1} \ \varepsilon_{\tilde{c},t+1} \ 0 \ldots 0]'\).

The three remaining UC models set \(\kappa = 1\) in the state space systems of the 2-trend, 2-cycle UC.
model, the 2-trend, money cycle UC model, and the 2-trend, consumption cycle UC model. These are versions of the limiting DSGE models in which \( \kappa \to 1 \). The restriction on the state space of these UC models is that beyond the second column only zeros occupy the first row of the observation equations (20), (24), and (26). Thus, we are able to compare DSGE-PVMs with \( \kappa \) estimated on \((0, 1)\) to limiting DSGE models in which \( \kappa \to 1 \) on our Canadian-U.S. sample. This provides an empirical appraisal of the EW hypothesis.

4b. The UC Model and Its Likelihood Function

We label the 2-trend, 2-cycle UC model with \( \kappa \in (0, 1) \) \( UC_{2,2,\kappa} \). Likewise, \( UC_{2,\tilde{m},\kappa} \) and \( UC_{2,\tilde{c},\kappa} \) denote the 2-trend, money cycle and 2-trend, consumption cycle, \( \kappa \in (0, 1) \) UC models. The state space systems of \( UC_{2,2,\kappa} \), \( UC_{2,\tilde{m},\kappa} \), and \( UC_{2,\tilde{c},\kappa} \) are (20) and (23), (24)–(25), and (26)–(27), respectively. These state space systems represent the dynamics of \( Y_t = \begin{bmatrix} e_t & m_t & c_t \end{bmatrix}' \) restricted by the DSGE-PVM and permanent-transitory specifications of \( m_t \) and \( c_t \). These state space systems are mapped into the Kalman filter to evaluate the likelihood function as proposed by Harvey (1989) and Hamilton (1994). We denote the likelihood \( L(Y_t | \Gamma_{2,i,\kappa}, UC_{2,i,\kappa}) \), where \( i = 2, \tilde{m}, \tilde{c} \) and \( \Gamma_{2,i,\kappa} \) is the parameter vector of \( UC_{2,i,\kappa} \). The parameter vector of \( UC_{2,2,\kappa} \) contains \( 11 + k_{\tilde{m}} + k_{\tilde{c}} \) elements, \( \Gamma_{2,2,\kappa} = [\kappa \ \alpha_1 \ ... \ \alpha_{k_{\tilde{m}}} \ \theta_1 \ ... \ \theta_{k_{\tilde{c}}} \ \mu^* \ a^* \ \sigma_\mu \ \sigma_\alpha \ \sigma_{\tilde{m}} \ \sigma_{\tilde{c}} \ \sigma_{\epsilon_{a,t}} \ \sigma_{\epsilon_{t}} \ \pi_{e,0} \ \pi_{e,t} \ \pi_{e,a}]' \).

We add the parameters \( \varrho_{a,\tilde{c}}, \pi_{e,0}, \pi_{e,t} \), and \( \pi_{e,a} \) to \( \Gamma_{2,2,\kappa} \) to better fit the UC models to the data. For example, the Canadian-U.S. TFP differential exhibits more variation than \( c_t \) if the correlation coefficient of innovations to \( a_t \) and \( \tilde{c}_t \), \( E\{\varepsilon_{a,t}\varepsilon_{\tilde{c},t}\} = \varrho_{a,\tilde{c}} \), is negative. The remaining three parameters allow for an unrestricted exchange rate intercept, \( \pi_{e,0} \), a linear exchange rate time trend, \( \pi_{e,t} \), and a factor loading on the Canadian-U.S. TFP differential, \( \pi_{e,a} \), that differs from negative one for the \((1, 2)\) element in the matrix of the observation equation systems (20), (24), and (26). Note that the factor loading on the permanent component of \( m_t \) remains (normalized to) one.

---

11A related example is Harvey, Trimbur, and van Dijk (2007) who use Bayesian methods to estimate permanent-transitory decompositions of aggregate time series, but without rational expectations cross-equation restrictions.

The parameter vectors of the other five UC models are smaller. The $UC_{2,\bar{m},\kappa}$ model drops two plus $k_{\bar{c}}$ parameters from $\Gamma_{2,\bar{m},\kappa} = [\kappa \ \alpha_1 \ \ldots \ \alpha_{k_{\bar{m}}} \ \mu^* \ \sigma^*_\mu \ \sigma^*_a \ \sigma^*_{\bar{m}} \ \pi_{e,0} \ \pi_{e,t} \ \pi_{e,a} \ \pi_{e,\bar{m}}]'$, while adding the factor loading on $\bar{m}_t$ for $c_t, \pi_{c,\bar{m}}$. The factor loading $\pi_{m,\bar{c}}$ enters the parameter vector of $UC_{2,\bar{m},\kappa}$, while $\alpha_1 \ \ldots \ \alpha_{k_{\bar{m}}} \ \text{and} \ \sigma^*_{\bar{m}}$ are dropped from $\Gamma_{2,\bar{c},\kappa} = [\kappa \ \theta_1 \ \ldots \ \theta_{k_{\bar{c}}} \ \mu^* \ \sigma^*_\mu \ \sigma^*_a \ \sigma^*_{\bar{c}} \ \theta^*_a \ \pi_{e,0} \ \pi_{e,t} \ \pi_{e,a} \ \pi_{m,\bar{c}}]'$. The parameter vectors of the UC models $UC_{2,2,\kappa=1}$, $UC_{2,\bar{m},\kappa=1}$, and $UC_{2,\bar{c},\kappa=1}$ are identical to $\Gamma_{2,2,\kappa}$, $\Gamma_{2,\bar{m},\kappa}$, and $\Gamma_{2,\bar{c},\kappa}$ except that $\kappa = 1$.

4c. The Data

The sample runs from 1976Q1 to 2004Q4, $T = 116$. We have observations on the Canadian dollar – U.S. dollar exchange rate (average of period). The Canadian monetary aggregate is M1 in current Canadian dollars, while for the U.S. it is the Board of Governors Monetary Base (adjusted for changes in reserve requirements) in current U.S. dollars. Consumption is the sum of non-durable and services expenditures in constant local currency units. The aggregate quantity data is seasonally adjusted and converted to per capita units. The data is logged and multiplied by 100, but is neither demeaned nor detrended.

4d. Estimation Methods

The likelihood function of the UC models do not have analytic solutions. We approximate the likelihoods $L(Y_t | \Gamma_{2,i,\kappa=1}, UC_{2,i,\kappa=1})$ and $L(Y_t | \Gamma_{2,i,\kappa}, UC_{2,i,\kappa})$ with posterior distributions of $\Gamma_{2,i,\kappa=1}$ and $\Gamma_{2,i,\kappa}$, generated by the MCMC replications of the random walk MH simulator. Our estimates of $\Gamma_{2,i,\kappa=1}$ and $\Gamma_{2,i,\kappa}$ and marginal likelihoods build on the Bayesian estimation tools of Fernández-Villaverde and Rubio-Ramírez (2004), Rabanal and Rubio-Ramírez (2005), Geweke (1999, 2005), and Gelman, Carlin, Stern, and Rubin (2004). The MH simulator is asked to create 1.5 million MCMC draws from the posterior. The initial 750,000 draws are treated as a burn-in sample and therefore discarded. We base our estimates on the remaining 750,000 draws from the posteriors of the $UC_{2,2,\kappa=1}$, $UC_{2,\bar{m},\kappa=1}$, $UC_{2,\bar{c},\kappa=1}$, $UC_{2,2,\kappa}$, $UC_{2,\bar{m},\kappa}$, and $UC_{2,\bar{c},\kappa}$ models.\textsuperscript{14}

\textsuperscript{13}Canadian consumption includes semi-durable expenditures.

\textsuperscript{14}The posterior distributions are based on acceptance rates of between 25 and 36 percent. Besides the 750,000 MCMC draws used to compute the moments reported below, four more sequences of 750,000 MCMCs are generated from disparate starting
4e. Priors

The second column of table 4 (5) list the priors of $\Gamma_{2,i,k=1} (\Gamma_{2,i,k})$, $i = 2$, $\bar{m}$, $\bar{c}$. Under a normal prior, the first element is the degenerate mean and second its standard deviation. The inverse-gamma priors are parameterized by its degrees of freedom, the first element, and its mean, the second element. The left and right end points of a uniform prior is denoted by its first and second elements.

We choose degenerate priors for the lag lengths of the MA($k\bar{m}$) of $\bar{m}_t$ and AR($k\bar{c}$) of $\bar{c}_t$ that set $k\bar{m} = k\bar{c} = 2$. Normal priors for the MA ($\alpha_1$ and $\alpha_2$) and AR ($\theta_1$ and $\theta_2$) coefficients allow for disparate transitory behavior in $\bar{m}_t$ and $\bar{c}_t$. The prior means of $\alpha_1$, $\alpha_2$, $\theta_1$, and $\theta_2$ guarantee that the relevant eigenvalues are strictly less than one. The eigenvalues of the MA(2) (AR(2)) of $\bar{m}_t$ ($\bar{c}_t$) are $0.60 \pm 0.20i$ (0.95 and -0.10). The standard deviation of the normal priors of the MA and AR coefficients provide for a wide set of realizations for $\alpha_1$, $\alpha_2$, $\theta_1$, and $\theta_2$. However, when a draw generates an eigenvalue greater than one (in absolute value) for either the MA or AR coefficients, the draw is discarded. Nonetheless, the MA and AR priors admit transitory cycles in cross-country money and consumption that allow for power at the business cycle frequencies, if the data wants.

We opt for priors of $\mu^*$ and $a^*$ that rely on the Canadian–U.S. money stock and consumption differentials samples. Since $\mu^*$ and $a^*$ represent deterministic trend growth, we ground the priors on normal distributions. The prior standard deviations of $\mu^*$ and $a^*$ match sample moments.

Priors on the standard deviations of the shock innovations reflect standard practice for estimating DSGE models with Bayesian methods. For example, Adolfson, Laséen, Lindé, and Villani (2007) employ inverse-gamma priors for the standard deviations of the shock innovations of their sticky price open economy DSGE model. However, there is a lack of good information about $\sigma_{\mu}$, $\sigma_{\alpha}$, $\sigma_{\bar{m}}$, and $\sigma_{\bar{c}}$. This explains why we impose a prior with two degrees of freedom, which forces these standard deviations to values to assess across chain and with chain convergence. We compute the $\hat{R}$ statistic of Gelman, Carlin, Stern, and Rubin (2004) to evaluate across chain across and the separated partial means test of Geweke (2005) convergence, which is distributed asymptotically $\chi^2$. Across the 77 parameters of the six UC models, the two largest $\hat{R}$s are 1.20 and 1.04, while Gelman, et al suggest a $\hat{R}$ of about 1.10. On five subsamples, The Geweke separated partial means test has no $p$–value smaller than 0.21 across the six UC models and five MCMC simulation sequences.
be positive. On the other hand, we attach a normally distributed prior to the correlation of innovations to $\alpha_t$ and $\tilde{c}_t$, $\rho_{\alpha,\tilde{c}}$. Its mean is negative to capture our prior that $\alpha_t$ is smoother than $c_t$. Since we have no information about the extent of the smoothness, the mean is $-0.5$ with a standard deviation of 0.2 that places draws close to negative one or zero in the 95 percent coverage interval of the prior. Draws greater than one or less than negative one are ignored. The correlation of innovations to $\mu_t$ and $\tilde{m}_t$ is fixed at zero because our belief is that the sources and causes of permanent and transitory monetary shocks are orthogonal.

The exchange rate intercept and linear time trend priors are set according to a linear regression of the sample Canadian dollar–U.S. dollar exchange rate on these objects. This motivates our choice of normally distributed priors for $\pi_{e,0}$ and $\pi_{e,t}$ and is the source of their degenerate means and standard deviations.

The remaining factor loadings have priors that reflect a dearth of information on our part. The uniform priors of $\pi_{e,a}$, $\pi_{c,\tilde{m}}$, and $\pi_{c,\tilde{m}}$ are wide and include zero. If, for example, $\pi_{e,a}$ is small it indicates the inadequacy of the balanced growth restriction and the impact of permanent fluctuations in Canadian–U.S. TFP differentials on the exchange rate. The same holds for the response of $c_t (m_t)$ to transitory movements in the Canadian–U.S. money stock (consumption) differential.

The $UC_{2,i,\kappa}$ models have only one ‘economic’ parameter, the DSGE-PVM discount factor $\kappa \equiv \frac{1}{1 + \rho}$, in common. We adopt the Engel and West (2005) prior for $\kappa$. They argue that it is necessary for $\kappa \in [0.9, 0.999]$ to generate an approximate random walk exchange rate from the standard-PVM. Hence, our prior on $\kappa$ is constructed to provide information about the EW hypothesis from the posteriors of the $UC_{2,i,\kappa}$ models. We impose an inverse-gamma prior on the DSGE-PVM discount factor $\kappa$, which follows Del Negro and Schorfheide (2006). The degenerate prior means of $\kappa = 0.988$ and $\exp([a^* = 0.158]/400)$ imply an annual average real world interest rate of about five percent. Although a five percent real world interest rate is large for the floating rate period, the standard deviation of 0.038 guarantees draws for $\kappa$ that cover a wide interval. However, MCMC draws from the random walk MH simulator of the $UC_{2,i,\kappa}$ models obey the EW prior because we ignore draws for which $\kappa \notin [0.9, 0.999]$. 

23
5. RESULTS

This section presents the results of implementing our empirical strategy. Tables 4 and 5 provide the posterior means and standard deviations of the $\Gamma_{2,i,\kappa=1}$ and $\Gamma_{2,i,\kappa}$ vectors, $i = 2$, $\tilde{m}$, $\tilde{c}$, for the $UC_{2,2,\kappa=1}$, $UC_{2,\tilde{m},\kappa=1}$, $UC_{2,\tilde{c},\kappa=1}$, $UC_{2,2,\kappa}$, $UC_{2,\tilde{m},\kappa}$, and $UC_{2,\tilde{c},\kappa}$ models. We present densities of the prior and posteriors of $\kappa$ for the latter three UC models in figure 1. The posterior distributions of the six UC models are used to construct the marginal likelihoods of the six UC model, as described by Fernández-Villaverde and Rubio-Ramírez (2004), Rabanal and Rubio-Ramírez (2005), and Geweke (1999), to conduct inference across these models. We also report the factor loadings on the CDN$/US$ exchange rate of the transitory components of the Canadian-U.S. money stock and consumption differentials, unconditional variance ratios of the present discounted value of the shock innovations to the $CDN$/US$ exchange rate, FEVDs of the trend-cycle decomposition of the exchange rate with respect to these shocks, and summary statistics of trend-cycle decompositions in tables 6, 7, 8, and 9, respectively. Figures 2, 3, and 4 plot the trend-cycle decomposition of the $CDN$/US$ exchange rate.

5a. Parameter Estimates

Tables 4 and 5 list the posterior means and standard deviations of the parameters of the six UC models. Estimates of the limiting DSGE models appear in table 4. These are $UC_{2,2,\kappa=1}$, $UC_{2,\tilde{m},\kappa=1}$, $UC_{2,\tilde{c},\kappa=1}$. These three models exhibit persistence in the transitory components of the Canadian-U.S. money and consumption differentials, $\tilde{m}_t$ and $\tilde{c}_t$. For example, the $UC_{2,\tilde{m},\kappa=1}$ ($UC_{2,\tilde{c},\kappa=1}$) model yield AR (MA) estimates that imply the half life of shock to $\tilde{c}_t$ ($\tilde{m}_t$) is 17 (7) years.\(^{15}\) However, only $\tilde{c}_t$ is persistent in the $UC_{2,2,\kappa=1}$ model. The half life of a shock to $\tilde{m}_t$ is less than two quarters, while for $\tilde{c}_t$ it is between nine and ten years. Note also that the priors and posterior means of the MA coefficients, $\alpha_1$ and $\alpha_2$, only differ for the $UC_{2,\tilde{m},\kappa=1}$ model. Although the posterior means of the AR coefficients have moved away from the prior means, a one standard deviation of the posterior of $\theta_2$ covers zero for the $UC_{2,2,\kappa=1}$ and $UC_{2,\tilde{c},\kappa=1}$ models.

The posterior means of $\mu^*$ and $\alpha^*$ show that Canada experiences slower (faster) trend money

\(^{15}\)The half life equals $\log(0.5)/\log(q)$, where $q$ is the largest modulus of the companion matrix of the AR or MA coefficients.
(TFP) growth than for the U.S. from 1976Q1 to 2004Q4. Trend U.S. money growth is on average about 0.05 percent higher annually according to the posteriors of the $UC_{2,2,\kappa=1}$, $UC_{2,\tilde{m},\kappa=1}$, and $UC_{2,\tilde{c},\kappa=1}$ models. Across these models, $a^* \approx 0.16$ indicates Canadian deterministic trend TFP growth dominates its U.S. counterpart by about 0.06 percent at an annual rate.

The $UC_{2,2,\kappa=1}$, $UC_{2,\tilde{m},\kappa=1}$, and $UC_{2,\tilde{c},\kappa=1}$ models show differences across estimates of the posterior means of the shock innovation standard deviations the Canadian-U.S. sample. Only the estimated impulse structure of the $UC_{2,\tilde{m},\kappa=1}$ model is dominated by movements in the permanent innovations of the Canadian–U.S. money differential shock, $\sigma_\mu$. The converse is that this model yields the smallest posterior means of the standard deviation of the Canadian–U.S. TFP differential shock and $\tilde{m}_t$ shock innovations, $\sigma_a$ and $\sigma_{\tilde{m}}$. The $UC_{2,\tilde{c},\kappa=1}$ model yields the largest estimates of $\sigma_a$ and $\sigma_{\tilde{c}}$, but these posterior means are about the same magnitude. Note also that the correlation of the innovations to the Canadian–U.S. TFP differential shock and $\tilde{c}_t$ shock is estimated to be $\varrho_{a,\tilde{c}} = -0.88$ and $-0.95$ by the $UC_{2,2,\kappa=1}$ and $UC_{2,\tilde{c},\kappa=1}$ models, respectively. Thus, these models are consistent with the Canadian–U.S. TFP trend differential being more volatile than observed Canadian–U.S. consumption.

Estimates of the exchange rate intercept and linear time trend indicate that the $UC_{2,\tilde{m},\kappa=1}$ model provides the largest value for the US$ in steady state and the largest deterministic growth rate for the CDN$/$US$ exchange rate. The posterior means of $\pi_{e,0}$ and $\pi_{e,t}$ imply that the steady state CDN$/$US$ exchange rate is 1.23 with a deterministic annual growth rate of about 0.8 percent. For the $UC_{2,2,\kappa=1}$ ($UC_{2,\tilde{c},\kappa=1}$) model, the analogous values are 1.10 (1.03) and 0.3 (0.2) percent per annum. Thus, the $UC_{2,\tilde{m},\kappa=1}$ model places more emphasis on deterministic elements to fit the data compared to the other two UC models of the limiting DSGE-PVM.

The remaining coefficients are the factor loadings $\pi_{e,a}$, $\pi_{e,\tilde{m}}$, and $\pi_{e,\tilde{c}}$. The posterior mean estimates of $\pi_{e,a}$ $-2.68$ and $-9.02$ reveal that there are statistically and economically large deviations from the balanced growth path by the $UC_{2,2,\kappa=1}$ and $UC_{2,\tilde{m},\kappa=1}$ models. The $UC_{2,\tilde{c},\kappa=1}$ model is closer to satisfying the balanced growth hypothesis that $\pi_{e,a} = -1$. This UC model has a posterior mean of $-0.72$ for $\pi_{e,\tilde{c}}$ whose two standard deviation interval contains the balanced growth restriction. The response
of the Canadian–U.S. money stock differential to $\tilde{c}_t$ is also close to negative one for the $UC_{2,\tilde{c},\kappa=1}$ because the posterior mean of $\pi_{m,\tilde{c}} = -0.90$ with a standard deviation of 0.21. The $UC_{2,\tilde{m},\kappa=1}$ model reveals that a one percent rise in $\tilde{c}_t$ results in a 4.4 percent rise in the Canadian–U.S. consumption differential.

The key economic parameter of the DSGE-PVM is its discount factor $\kappa$. Table 5 lists the posterior means and standard deviations of the $\Gamma_{2,\kappa}, \Gamma_{2,\tilde{m},\kappa}$, and $\Gamma_{2,\tilde{c},\kappa}$ vectors that include estimates of $\kappa$. Aside from the inclusion of the prior, posterior mean, and standard deviation $\kappa$ at the top of table 5, the posterior means and standard deviations of the remaining coefficients resemble those reported on table 4. The only notable exceptions are that the posterior means of $\sigma_a, \sigma_{\tilde{c}}, \pi_{e,a},$ and $\pi_{e,\tilde{c}}$ are smaller for the $UC_{2,\tilde{c},\kappa}$ model compared to its cousin with the calibration $\kappa = 1$. The result is that $\sigma_{\mu}$ is the largest innovation shock standard deviation of the $UC_{2,\tilde{c},\kappa}$ model. Also, this UC model and the data produce an estimate of $\pi_{e,a}$ whose one standard deviation coverage interval contains negative one. Thus, the $UC_{2,\tilde{c},\kappa}$ model is closer to the balanced growth hypothesis and relies to a greater extent on permanent shocks to the Canadian–U.S. money stock differential.

The posterior means of $\kappa$ range from 0.966 for the $UC_{2,\tilde{c},\kappa}$ model, 0.974 for the $UC_{2,\tilde{m},\kappa}$ model, to the largest estimate of 0.9962 for the $UC_{2,\tilde{c},\kappa}$ model. These estimates are consistent with annual world real interest rates of 15.1, 11.4, and 1.7 percent given the posteriors of the $UC_{2,\tilde{c},\kappa}$, $UC_{2,\tilde{m},\kappa}$ and $UC_{2,\tilde{c},\kappa}$ models, respectively. Although the $UC_{2,\tilde{c},\kappa}$, $UC_{2,\tilde{m},\kappa}$ models have posteriors that suggest unreasonably large world real interest rates, these UC models yield 95 percent coverage intervals whose upper end is 0.999. The $UC_{2,\tilde{c},\kappa}$ model produces a posterior of $\kappa$ with a 95 percent coverage interval whose lower end equals 0.987. This value of $\kappa$ is greater than the posterior means of $\kappa$ of the $UC_{2,\tilde{c},\kappa}$ for the $UC_{2,\tilde{m},\kappa}$ models. Thus, the $UC_{2,\tilde{c},\kappa}$ model generates a posterior distribution of $\kappa$ that is to the right of those produced by the $UC_{2,\tilde{m},\kappa}$, $UC_{2,\tilde{m},\kappa}$ models.

Figure 1 reinforces the idea that the posteriors of the $UC_{2,\tilde{c},\kappa}$ and $UC_{2,\tilde{m},\kappa}$ models yield estimates of $\kappa$ that are shifted to the right of those of the $UC_{2,\tilde{c},\kappa}$ model. Posterior densities of $\kappa$ are plotted in figure 1 for these UC models, along with the density of the inverse-gamma prior of $\kappa$ on the EW prior of $\kappa \in [0.9, 0.999]$. The solid (black) line is the density of the $\kappa$ prior and is close to the posterior density.
of $\kappa$ derived from the $UC_{2,2,\kappa}$ model, which is the dashed (blue) line. The $UC_{2,\bar{m},\kappa}$ model generates a posterior density of kappa, the dot-dash (green) plot, which moves off the prior by placing less weight on $\kappa$s less than 0.97 and more weight above this value. The dot-dot (red) plot is the density of $\kappa$ from the posterior of the $UC_{2,\bar{c},\kappa}$ model. This density is deflated by ten percent for ease of comparison to the other densities. A striking feature of figure 1 is that the posterior of the $UC_{2,\bar{c},\kappa}$ model pushes $\kappa$ off of its prior because its mass lays between 0.98 and 0.999.

Table 6 contains the posterior means of the exchange rate factor loadings with respect to $\bar{m}_t$ and $\bar{c}_t$, the $\delta_{\bar{m},i}$s and $\delta_{\bar{c},i}$s.\(^\dagger\) A striking aspect of the estimates of $\delta_{\bar{m},0}$, $\delta_{\bar{m},1}$, and $\delta_{\bar{m},2}$ is that the response of the CDN$/US$ exchange rate to innovations in $\bar{m}_t$ is economically small for either the $UC_{2,2,\kappa}$ or $UC_{2,\bar{m},\kappa}$ models. The large posterior standard errors on these factor loading also indicate the imprecision the Canadian–U.S. data give to these estimates. The data have less problems yielding a precise estimate of $\delta_{\bar{c},0}$ for the $UC_{2,2,\kappa}$ model. The posterior mean of this factor loading shows that the exchange rate falls by 0.6 percent given an one percent increase in $\bar{c}_t$. These estimates drops to $-0.33$ for the $UC_{2,\bar{c},\kappa}$ model. Also, the associated 95 percent coverage interval contains zero. In summary, the $UC_{2,2,\kappa}$, $UC_{2,\bar{m},\kappa}$, and $UC_{2,\bar{c},\kappa}$ models have posteriors in which there is either a negligible exchange rate response to $\bar{m}_t$ shocks or an economically large negative reaction by the CDN$/US$ exchange rate to $\bar{c}_t$ fluctuations. However, the latter exchange rate response can be estimated imprecisely.

5b. Unconditional Variance Ratios and FEVDs of the Exchange Rate

Tables 7 and 8 present unconditional variance ratios and FEVDs computed using the posteriors of the $UC_{2,2,\kappa}$, $UC_{2,\bar{m},\kappa}$, and $UC_{2,\bar{c},\kappa}$ models. We calculate the variances of the present discounted values (PDVs) of the Canadian–U.S. money, TFP, and consumption differential shock innovations using the equilibrium currency return generating equation (17) and the restrictions of the UC models which yield estimates of $\kappa$. The variance ratios are these values divided by the sample variance of the CDN$/US$ exchange rate ( = 2.04). According to the unconditional variance ratios, only permanent shocks to the Canadian–US money differential, $\varepsilon_{\mu,t}$, and the TFP differential, $\varepsilon_{a,t}$, explain variation in the CDN$/US$ exchange rate.

\(^\dagger\)For the $UC_{2,\bar{m},\kappa}$ and $UC_{2,\bar{c},\kappa}$ models, the relevant factor loadings are multiplied by $1 - \pi_{\varepsilon,\bar{m}}$ or $1 - \pi_{\varepsilon,\bar{c}}$. 

27
exchange rate. The variances of the PDVs of shock innovations to $\tilde{m}_t$ and $\tilde{c}_t$ are small and lack precision. Note that except for the $UC_2,\tilde{m},\kappa$ model, the variance of the PDV of $\epsilon_{a,t}$ is larger than that of $\epsilon_{\mu,t}$.

We report FEVDs in table 8 with implications similar to the unconditional variance ratios. The top panel of figure 8 shows that the posterior of the $UC_2,\tilde{m},\kappa$ yields a FEVD in which the Canadian–US TFP differential shock $\epsilon_{a,t}$ makes a large and increasing contribution to CDN$/US$ exchange rate fluctuations at longer forecast horizons. The Canadian–US money differential shock $\epsilon_{\mu,t}$ remains economically important for CDN$/US$ exchange rate movements out to a three to five year forecast horizon, but shocks to $\tilde{m}_t$ and $\tilde{c}_t$ are unimportant at any forecast horizon. Much the same is true for the FEVDs found using the posterior of $UC_2,\tilde{m},\kappa$. However, the relative shares of the $\epsilon_{\mu,t}$ and $\epsilon_{a,t}$ shocks are unchanged at a two-thirds/one-third split from the one quarter to ten year forecast horizons.

The posterior of the $UC_2,\tilde{c},\kappa$ model imbues a slowly changing dynamic to the CDN$/US$ exchange rate FEVDs as found in the bottom panel of table 8. The $\epsilon_{\mu,t}$ and $\epsilon_{a,t}$ shocks are responsible for about 60 and 40 percent, respectively, of fluctuations in the CDN$/US$ exchange rate at the short horizons. At a 10 year horizon, the contribution of $\epsilon_{\mu,t}$ ($\epsilon_{a,t}$) only falls (rises) to 55 (45) percent. Thus, only the posterior of the $UC_2,\tilde{c},\kappa$ model predicts that permanent shocks to the Canadian–US money differential dominate CDN$/US$ exchange rate movements at the longer forecast horizons.

5c. Trend-Cycle Decompositions

Trend-cycle decompositions of the CDN$/US$ exchange rate and Canadian–U.S. money and consumption differentials are plotted in figures 2 and 3 with summary statistics given in table 9. The posteriors of the $UC_2,\kappa$, $UC_2,\tilde{m},\kappa$, and $UC_2,\tilde{c},\kappa$ models are run through the Kalman smoother to create the trend-cycle decompositions and summary statistics. Figures 2 and 3 and table 9 contain moments that are averages over the 750,000 draws from the UC model posteriors. We label trend exchange rate growth $\Delta e^\tau$ in table 9.

The top window of figure 2 contains plots of the CDN$/US$ exchange rate and smoothed

\footnote{The FEVDs are computed using the vector ECM implied by equation (16) and the permanent-transitory specifications of Canadian-U.S. money and consumption differentials. The vector ECM is placed in state space form as outlined by Heqc, Palm, and Urbain (2000) and iterated upon to create the FEVDs of table 8.}
trends taken from the posteriors of the $UC_{2,2,\kappa}$ and $UC_{2,\tilde{c},\kappa}$ models.\textsuperscript{18} The solid (black) line is $e_t$, the log of the actual CDN/US$ exchange rate. The smoothed trends of the $UC_{2,2,\kappa}$ and $UC_{2,\tilde{c},\kappa}$ models are the dashed (blue) and dotted (red) plots, respectively. Note that these UC models generate smoothed CDN/US$ exchange rate trends that are more volatile than the actual exchange rate. The top row of table 9 indicate that the posteriors of the $UC_{2,2,\kappa}$ and $UC_{2,\tilde{c},\kappa}$ models generate standard deviations of $\Delta e^\tau$ are 2.66 and 2.44, respectively. The standard deviation of $\Delta e^\tau$ equals 2.04.

The smoothed CDN/US$ exchange rate cycles appear in the bottom window of figure 2. The dotted (blue) line is the smoothed exchange rate cycle, $\tilde{e}_t$, based on the posterior of the $UC_{2,2,\kappa}$ model, while the dotted (red) line is associated with the $UC_{2,\tilde{c},\kappa}$ model. Although the former $\tilde{e}_t$ exhibits more variability than the latter (the standard deviations are 3.68 and 2.44), these $\tilde{e}_t$s are persistent with AR1 correlation statistics of 0.97 and 0.98. Note that only the posterior of the $UC_{2,\tilde{m},\kappa}$ model yields (close to) a non-zero correlation for $\Delta e^\tau$ and $\tilde{e}$, according to table 9.

Figure 3 shows the smoothed permanent-transitory decompositions of the Canadian-U.S. money and consumption differentials. The actual differentials and smoothed trends appear in the top row of windows, while the smoothed cycles are found in the bottom row of windows. The Canadian-U.S. money (consumption) differentials are the right (left) side windows. The posterior of the $UC_{2,2,\kappa}$ model produces a money trend, $\mu_t$, that almost perfectly mimics the actual Canadian-U.S. money differentials, as found in the top left window of figure 3. The result is that the smoothed $\tilde{m}_t$ is much less volatile, a standard deviation of 0.68, compared to a standard deviation of 1.62 for $\mu_t$. The bottom left window of figure 3 shows a saw-toothed pattern in $\tilde{m}_t$, conditional on the posterior of the $UC_{2,2,\kappa}$ model. This explains the AR1 correlation statistic of $-0.68$ for $\tilde{m}_t$ that appears in the middle of second column of table 9.

Table 9 reveals that the posterior of the $UC_{2,\tilde{c},\kappa}$ model produces a smoothed money trend, $\mu_t$, that is about as volatile as does the $UC_{2,2,\kappa}$ model. The relevant standard deviations are 1.62 and 1.71

\textsuperscript{18} We do not present the trend-cycle decompositions based on the posterior of the $UC_{2,\tilde{m},\kappa}$ model because its log marginal likelihood is far below those of the other UC models. Table 9 includes standard deviations of $\Delta e^\tau$ and $\tilde{e}$ from the posterior of the $UC_{2,\tilde{m},\kappa}$ model that are larger by a factor of 30 or compared to these statistics from the $UC_{2,2,\kappa}$ and $UC_{2,\tilde{c},\kappa}$ models, which is a signal of its lack of acceptance by our Canadian-U.S. sample.
in the second and fourth columns of table 9 for the smoothed money growth trend of these UC models. However, smoothed $\Delta \mu$ and $\Delta e^T$ share a positive correlation of 0.62 only in the posterior of the $UC_{2,\tilde{c},\kappa}$ model as shown in the bottom half of the fourth column of table 9.

The posteriors of the $UC_{2,2,\kappa}$ and $UC_{2,\tilde{c},\kappa}$ models yield qualitatively similar plots for the smoothed TFP trend, $a_t$, and consumption cycle $\tilde{c}_t$ in the top right window of figure 3. These plots appear in the top right window of figure 3 as dashed (blue) for the and dotted (red) for the $UC_{2,2,\kappa}$ and $UC_{2,\tilde{c},\kappa}$ models, respectively, where observed cross country consumption is the solid (black) line. The smoothed $\Delta a$ is 50 percent more volatile for the $UC_{2,\tilde{c},\kappa}$ model than it is for the $UC_{2,2,\kappa}$ model. The posteriors of these UC models also produce correlations of $-0.71$ and $-0.85$ for $\Delta e^T$ and $\Delta a$, which suggest that rising U.S. TFP is associated with a depreciation in the Canadian dollar.

The bottom right window of figure 3 presents the smoothed $\tilde{c}_t$ of the $UC_{2,2,\kappa}$ and $UC_{2,\tilde{c},\kappa}$ models. The former cycle is the dashed (blue) line and the latter is the dotted (red) plot. These cycles are persistent because their AR1 correlation statistics 0.97 and 0.98, but the $UC_{2,2,\kappa}$ model generates a third less volatility in smoothed $\tilde{c}_t$ than found for the $UC_{2,\tilde{c},\kappa}$ model.

The posteriors of the $UC_{2,2,\kappa}$ and $UC_{2,\tilde{c},\kappa}$ models generate economically meaningful trends and cycles in the Canadian–U.S. $a_t$ and $\tilde{c}$. The smoothed TFP differential is falling in the latter 1970s, which reflects a greater productivity slowdown in the Canada. By the 1980s, Canadian TFP is growing more rapidly than in the U.S., which continues into the early 1990s. Subsequently, U.S. TFP recovers relative to Canadian TFP. At the end of the sample, the Canadian–U.S. TFP differential is expanding once more.

The smoothed $\tilde{c}_t$ has peaks and troughs that coincide with several U.S.-Canadian business cycle dates. For example, troughs in the posterior mean of $\tilde{c}_t$ appear in 1981 and 1990 which also represent recessions dates in the U.S. and Canada. Since the end of the 1990 – 1991 recession, the rise in $\tilde{c}_t$ points to persistent, but transitory, rise in U.S. consumption relative to Canada. Nonetheless, $\tilde{c}_t$ has been falling rapidly since a peak in late 2001, which corresponds to the end of the last U.S. recession.

The bottom row of table 9 shows that $\tilde{c}_t$ and $\tilde{e}_t$ are perfectly negatively correlated in the posteriors of the $UC_{2,2,\kappa}$ and $UC_{2,\tilde{c},\kappa}$ models. The negative correlation of the transitory component of the
exchange rate with \( \tilde{\epsilon}_t \) help to interpret the CDN/US$ exchange rate fluctuations. Peaks in the transitory component of the CDN/US$ exchange rate occur either at or shortly after the end of recessions. For example, the smoothed CDN/US$ exchange rate cycles have a tendency to peak and trough around dates usually associated with U.S. and Canadian business cycle dates (i.e., the late 1970s, early 1990s, and 2001). A specific case is the peak in \( \tilde{\epsilon}_t \) during the 1990 – 1991 recession in the U.S., which is a moment at which the Canadian dollar approached par against the U.S. dollar. An exception is the end of the 2001 recession when the Canadian dollar reached a low of nearly 0.62 to the U.S. dollar.

5d. Comparing the UC models

The bottom row of table 4 reports the log marginal likelihoods, \( \ln \hat{L} \) of the \( UC_{2,\kappa=1} \), \( UC_{2,\tilde{m},\kappa=1} \), and \( UC_{2,\tilde{c},\kappa=1} \) models. These marginal likelihoods show that our Canadian-U.S. sample gives most support \( UC_{2,\tilde{c},\kappa=1} \) model. The difference between this model and the \( UC_{2,\kappa=1} \) model is about 29, or the Bayes factor prefers the UC model with only transitory consumption. For the data to give more credence to the latter model, its prior probability must be raised by the prior probability of the \( UC_{2,\tilde{c},\kappa=1} \) model multiplied by \( 4.7 \times 10^{12} \) \( = \exp(29.18) \). Since the magnitude of this factor is large, it seems unreasonable to include the transitory money shock in the UC model when \( \kappa \) is calibrated to one.

The last row of table 5 contains the log marginal likelihoods of the \( UC_{2,\kappa} \), \( UC_{2,\tilde{m},\kappa} \), and \( UC_{2,\tilde{c},\kappa} \) models. The ranking of these models matches that of the UC models with the \( \kappa = 1 \) calibration. The \( UC_{2,\tilde{m},\kappa} \) model dominates the \( UC_{2,\kappa} \) and \( UC_{2,\tilde{m},\kappa} \) models. A key reason is that the posteriors of these models yield economically implausible estimates of the DGSE-PVM discount factor \( \kappa \).

This raises the question of whether our Canadian-U.S. sample will find it difficult to choose between the \( UC_{2,\tilde{c},\kappa=1} \) and \( UC_{2,\tilde{c},\kappa} \) models. Our Canadian-U.S. sample favors the \( UC_{2,\tilde{c},\kappa=1} \) and \( UC_{2,\tilde{c},\kappa} \) models compared to the other four. The former UC model has a larger marginal likelihood, which suggest the data support it over the latter UC model with \( \kappa \in [0.9, 0.999] \). This choice relies on the belief that scaling up the prior probability of the \( UC_{2,\tilde{c},\kappa} \) model by about 167.3 \( = \exp(5.12) \) is too large to be justified. If, on the other hand, this factor is regarded as inconclusive in rejecting the \( UC_{2,\tilde{c},\kappa} \) model, it can be argued that our Canadian–U.S. sample cannot pick between the \( UC_{2,\tilde{c},\kappa=1} \) and \( UC_{2,\tilde{c},\kappa} \) models.
models.\textsuperscript{19} We suggest that this is support for the EW hypothesis.

5e. Exchange Rate Dynamics as $\kappa \to 1$

Engel and West (2005) argue that the exchange rate will approximate a random walk when the discount factor is close to one and fundamentals have a unit root. Propositions 7 and 8 also predict that $\tilde{e}_t$ will collapse to random walk, as $\kappa \to 1$.

We extract evidence about the EW hypothesis from the posteriors of the $UC_{2,2,\kappa}$ and $UC_{2,\tilde{c},\kappa}$ models. The focus is on these UC models because the $UC_{2,\tilde{c},\kappa=1}$ model attributes all CDN$/US$$\Dollar$ exchange rate movements to permanent shocks. The $UC_{2,2,\kappa}$ model is included for comparison. We conduct this comparison with $\kappa$s at the 16th and 84th percentiles, along with the largest $\kappa$s, from the $\Gamma_{2,2,\kappa}$ and $\Gamma_{2,\tilde{c},\kappa}$ vectors. For the $UC_{2,2,\kappa}$ ($UC_{2,\tilde{c},\kappa}$) model, the 16th percentile, 84th percentile, and largest $\kappa$s are 0.9425, 0.9883, and 0.9990 (0.9943, 0.9987, and 0.9990), respectively. Fixing $\kappa$ at these values, we simulate the $UC_{2,2,\kappa}$ and $UC_{2,\tilde{c},\kappa}$ models drawing 2000 sequences from the posteriors, discard the first 1000, run the Kalman smoother on the remaining 1000 sequences, and average the ensemble to generate CDN$/US$$\Dollar$ exchange rate cycles to respect the rational expectations hypothesis.

Figure 4 plots the smoothed CDN$/US$$\Dollar$ exchange rate cycles. The top (bottom) window contains the $\tilde{e}_t$ created from the posterior of the $UC_{2,2,\kappa}$ ($UC_{2,\tilde{c},\kappa}$) model. The dot-dash (blue), dotted (green), and dotted (red) lines are conditional on the 16th percentile, 84th percentile, and largest $\kappa$s, respectively. Across the top and bottom windows, the volatility of $\tilde{e}_t$ is compressed as $\kappa$ approaches 0.999. This is reflected in the standard deviations of $\tilde{e}_t$ that equal 4.44, 2.84, and 0.57 moving from the smallest to largest $\kappa$ for the $UC_{2,2,\kappa}$ model. The equivalent standard deviations are 3.74, 1.64, and 1.30 for the $UC_{2,\tilde{c},\kappa}$ model. Although the $UC_{2,2,\kappa}$ generates CDN$/US$$\Dollar$ exchange rate cycles that are smoother than at its posterior mean only for the largest $\kappa$s, the $UC_{2,2,\kappa}$ model is able to produce smoother exchange rate cycles at the 84th percentile and largest $\kappa$s. Thus, pushing $\kappa$ increases the smoothness of the CDN$/US$$\Dollar$ exchange rate cycle which we argue is evidence in support of the EW hypothesis.

\textsuperscript{19}Jefferys (1998) contends that Bayes factors differing by five is evidence about the two models just between ‘barely worth mentioning’ and considerably in favor of the model with the larger marginal likelihood.
6. Conclusion

Economists have little to say about the impact of policy on currency markets without an equilibrium theory of exchange rate determination that is empirically relevant. According to Engel and West (2005), the near random walk behavior of exchange rates explain the failure of equilibrium models to fit the data or to find any model that systematically beats it at out-of-sample forecasting. They conjecture that the standard-present value model (PVM) of exchange rates yields the random walk prediction when fundamentals are persistent and the discount factor is close to one.

This paper generalizes the Engel and West hypothesis. We find that the standard-PVM model places common trend and common cycle restrictions on the exchange rate and its fundamental. Under the former restriction and a discount factor close to one, the exchange rate collapses to a martingale. We also show that the exchange rate approximates a random walk when only the common cycle restriction holds and the discount factor approaches one.

We also construct a PVM of exchange rates from a two-country monetary dynamic stochastic general equilibrium (DSGE) model. The DSGE-PVM places restrictions on the exchange rate and fundamentals similar to those of the standard-PVM. For example, the exchange rate becomes a random walk when the DSGE-PVM discount factor approaches one. Thus, we generalize the Engel and West (2005) hypothesis to the wider class of open economy DSGE models.

Our empirical results support the view that it is difficult for the data to choose between a random walk exchange rate model and a DSGE-PVM with a discount factor estimated to be near one. Bayesian estimates of the DSGE-PVM also suggest that the Canadian dollar–U.S. dollar exchange rate is dominated by permanent shocks whether the discount factor is estimated or calibrated to one. Thus, the DSGE-PVM and the Canadian-U.S. sample yield estimates that support the Engel-West hypothesis. These results matter because the Engel-West hypothesis filtered through DSGE-PVM is part of the large class of open economy DSGE models. We expect this is a challenge to current open economy DSGE theories that hope to explain exchange rates fluctuations.

The level of fundamentals equals cross-country money netted with cross-country output calibrated to a unitary income elasticity of money demand. The money stocks (outputs) are measured in current (constant) local currency units and per capita terms. A constant and linear time trend are included in the level VARs. The LR statistics employ the Sims (1980) correction and have standard asymptotic distribution according to results in Sims, Stock, and Watson (1990). The case 2* and case 1 model definitions are based on Osterwald-Lenum (1992). MacKinnon, Haug, and Michelis (1999) provide five percent critical values of 8.19 (8.19) and 18.11 (15.02) for the case 2* model $\lambda$–max (trace) tests and 3.84 (3.84) and 15.49 (14.26) for the case 1 model. The common feature tests compute the canonical correlations of $\Delta e_t$ and $\Delta m_t - \Delta y_t$. The common feature null is all or a subset of the canonical correlations are zero. See Engle and Issler (1995) and Vahid and Engle (1993) for details.

†The summary statistics are taken the mean of the summary statistics of the posterior distributions of the trends and cycle of exchange rate, cross-country money, and cross-country consumption. The trend growth rate of the exchange rate is denoted $\Delta e^T$.
